ABSTRACT

The structural, Vibrational and Raman frequencies of 5,7-Dihydroxy-3-(4-hydroxyphenyl)chromen-4-one (genistein) has been studied in different solvents(toluene, ethanol, and water)using by *ab initio* Hartree–Fock(HF) and at the Becke-3-Lee-Yang-Parr (B3LYP) density functional theory (DFT) PCM method at the 6-311G basis set. The influence of these solvents on the optimized geometry, frequency, Mullikan charge distribution scheme and were studied. The thermodynamic functions of the titled compound have been computed at HF/6-311G and B3LYP/6-311G levels of theory.

Key words: genistein, HF, DFT, vibrational and Raman frequencies, Mullikan charge, thermodynamic properties.

INTRODUCTION

Almost all flavone derivatives have been identified from botanical sources[1]. They are commonly found in vascular plants as phenyl-benzopyrones with different basic structures. Many of the flavonoids found in plants exist as sugar derivatives (glycosides)[2]. Owing to their active role in photo sensitization, energy transport and cellular metabolism, many of flavone derivatives are ingredients for biochemical and pharmacological products used as human diet supplements[3].Flavones and flavonols found in plants are yellow compounds and are the main components of a numberof natural dyes used in textile dyeing since antiquity. Fustic, young fustic, quercitron, Persian berries, weld, dyer's broom and saw wort, which are important yellow dyes, all contain flavonoids such as quercetin, luteolin, fisetin, rhamnetin, genistein and morin[4].

Genistein, the principal soy isoflavone, is a molecule of great interest as a lead compound in anticancer drug design or as an innovative chemotherapeutic agent. Early works showed that genistein acted as an inhibitor of the tyrosine-specific protein kinases of the epidermal growth factor (EGF) receptor [5], and also inhibited the activity of topoisomerases [6].Recent studies suggests that genistein potentially inhibits proliferation of various cancer cells [7]and induces cell differentiation[8]and apoptosis [9,10]. Meanwhile, genistein also exhibits antiangiogenic[11]and antioxidant activities[12] that are important for cancer prevention. One of the most important advantages of genistein is its low toxicity in comparison with many current chemotherapeutic drugs[13]. However, the clinical utility of genistein is hindered by some of its disadvantages, including poor solubility in water, insufficient targeting of cancer cells, rapid *in vivo* metabolism and excretion, and low serum level after oral administration [14]. One obvious strategy to overcome these problems is to synthesize structurally modified genistein derivatives. A large amount of synthetic genistein analogues have been prepared in the last decade but yet meet the requirements for practical applications [14, 15]. An alternative strategy to the labor intensive organic synthesis is to design

appropriate drug delivery system that may overcome the shortcoming of genistein and greatly improve its performance in anticancer therapy [16, 17].

A number of papers have recently appeared in the literature concerning the calculation of vibrational assignments by quantum-chemistry methods [18]. These papers indicate that geometry optimization is a crucial factor in an accurate determination of computed vibrational frequencies. Moreover, it is known that the density functional theory (DFT) adequately takes into account electron correlation contributions, which are especially important in systems containing extensive electron conjugation and/or electron lone pairs. However, considering that as molecular size increases, computing-time also increases. To optimize computing-time the DFT level was used. It was proposed that the single-point calculation of magnetic shielding by DFT methods was combined with a fast and reliable geometry-optimization procedure at the molecular mechanics level. In most cases, in order to take into account correlation effects, post-Hartree-Fock calculations of organic molecules have been performed using (i) Møller-Plesset perturbation methods, which are very time consuming and hence applicable only to small molecular systems, and (ii) density functional theory (DFT) methods, which usually provide significant results at a relatively low computational cost. ab initio calculations were performed as an aid in assigning the normal modes to which the spectral lines correspond. DFT has proven to be the best theoretical approach for the study of flavone and derivatives[19,20], and for that reason we chose to use it here. Furthermore, good normal mode assignments are useful in extrapolating possible spectral changes to other flavone derivatives.

Literature survey reveals that to the best of our knowledge, no ab initio HF/DFT frequency calculations of genistein in different solvents have been reported so far. In this study, we have investigated the structural and electronic properties of genistein molecule theoretically, by performing ab initio calculations because of biological and medical importance of title compound.

MATERIALS AND METHODS

Computational Details:

The entire calculations performed at HF and DFT (B3LYP) levels on personal computer using Gaussian 09 W Revision B.01, program package[21]. Initial geometry generated from standard geometrical parameters minimized without any constraint in the potential energy surface at HF level, adopting the standard 6-31G basis set. The optimized structural parameters used in the vibrational wave number calculation sat the HF and DFT levels to characterize all stationary points as minima, i.e. the geometry optimization resulted in a planar geometry and no imaginary frequencies were observed in the calculated spectrum. In addition the effects of three solvents, toluene, ethanol and water were studied by means of the self-consistent reaction-field (SCRF) method based on PCM developed by Tomasi and coworkers[18]. It is one of the most widely used approaches. In this model, a solute is considered inside a cavity and the solvent as a structure less medium characterized by some parameters such as its dielectric constant, molar volume and polarizability. This consideration can substantially improve the simulation results for the electronic or vibrational spectroscopy of real molecular systems[19,20]. Finally, the calculated normal mode vibrational wave numbers provide thermodynamic properties also through the principle of statistical mechanics. Vibrational frequencies were computed on the optimized geometries in all media. By combining the results of the Gauss View (5.0) program with symmetry considerations, vibrational frequency assignments are made with a high degree of accuracy. No scale factor was used in the calculated frequencies.

RESULTS AND DISCUSSION

The Genistein assumed as Cs point group of symmetry and the optimized geometrical parameters of the title compound are calculated by ab initio HF and DFT(B3LYP) levels with the 6-311G basis set. The labeling of atoms in genistein is given in Figure 1. We designate the benzo ring in the chromone system as Ring A, the phenyl ring as Ring B and the pyrone ring as Ring C. The most optimized bond lengths and bond angles of this compound were calculated in gas phase and in toluene, ethanol and water, in order of increasing dielectric constants(1.0, 2.379, 24.55 and 78.39, respectively) and shown in Table 1. Comparing bond lengths of B3LYP with those of HF as a whole, the formers are on higher side than the later; because of it is well known that the DFT(B3LYP) method adequately takes into account electron correlation contributions which are especially important in systems containing extensive electron conjugation and/or electron lone pairs. As the result of solvent effect, the calculated geometries of genistein in solutions have some differences, but ethanol and water are almost same values, because of both solvents are polarities.

According to molecular structure of genistein have mainly three different bond lengths between different atom such as C-C,C-O, and O-H .Fig.2 shows the bond lengths between C-C. The bond length between C1-C2 has low value, when compared to other C-C bonds in the molecule, i.e the C1-C2 represent double bond in the molecule. The bonds C2-C3, C2-C14 and C3-C5 are showing higher values comparison of other all C-C bonds, because of these bonds represents C-C single bonds in the molecule. The other aromatic C=C bonds are showing different values depending upon the subsutuents.C5-C6 bond length is higher than other the aromatic C=C bonds, due to the reason C5 and C6 attached to carbonyl carbon (C3=O4) and hydroxyl group (O7-H22) respectively and C6-O7-H22 involve in hydrogen bond with O14 atom.

Fig.3. shows the calculated bond lengths between O-H in different solvents and HF and DFT methods. An O---H separation that is less than the sum of O and H vanderwaals radii (0.14 and 0.12 nm ,respectively) is assigned to the intermolecular hydrogen bonding[22].One intramolecular hydrogen bond is observed: the oxygen of the carbonyl group and the hydrogen of the 7- OH; the distance is show in table 1 in different media and different methods. The

O7-H22 bond length is have higher value than the O8-H28 and O18-H22 bond lengths in both methods and all solvents, because of the O7-H22 bond is involve in intramolecular hydrogen bond with O4 atom shown in fig.1.The bond angles between C6-O7-H22 is less than the other bond angles between C17-O10-H28 and C9-O10-H24 .

3. Table. Vibrational frequencies (cm^{-1}),IR intensities and Raman intensities of genistein in various solvents , the frequency shifts(Δ) in different solvents with respect to gas phase and their assignments DFT(B3LYP) /6-311G method.

Fig.4. represents the calculated bond lengths between O-H in different solvents and HF and DFT methods. The C-O bond lengths are different values due to the chemical environment, the C3-O4 bond length is very low value, it is represented by carbonyl group(C3=O4), C6-O7(C-O-H) is low value compared of other C9-O10(C-O-H) and C17-O18(C-O-H) bond lengths due to C6-O7 involve in the intramolecular hydrogen bond. In all solvents the bond angles are approximately the same in all the media, while the size of C2-C3-C5 and C1-C13-C12 increase with increasing solvent polarity. This is large variation is due to the intramolecular hydrogen bonding and the electrostatic interaction of the solute with the solvent.

Vibrational Assignments:

According to the theoretical calculations, genistein has a structure of Cs point group symmetry. The molecule has 30 atoms and 84 modes of fundamental vibrations. All the 84 fundamental vibrations are active in both IR absorption and Raman scattering. The vibrational wave numbers were calculated using the ab initio HF/6-311G and DFT(B3LYP)/6-311G level of theory to get the optimized geometry(Fig.1) under different media. The absence of imaginary values of wave numbers as the calculated vibrational spectrum confirms that the structure deduced corresponds to minimum energy.No scale factor was used in the calculated frequencies. Gauss view molecular visualization program was used to assign the calculated harmonic frequencies. The resulting vibrational wave numbers, IR intensities, Raman intensities for the optimized geometry of title compound and the proposed assignments, and also the frequency shifts in different solvents with respect to gas phase are given in table 2 and 3.The calculated IR spectra and Raman spectra plotted using Lorentizian band shape with a bandwidth of (FWHM) of 20 cm⁻¹as shown fig (6 -9) in different solvents.

The results shows that the frequency values at HF level are higher than the DFT method; the DFT partitions the electronic energy $E = E_t + E_v + E_j + E_{xc}$, where E_t , E_v , and E_j are electronic kinetic energy, electron nuclear attraction and electron-electron repulsion terms respectively. The electron correlation is taken into account in the DFT via the exchange-correlation term E_{xc} , which includes exchange energy arising from the antisymmetry of quantum mechanical wave function and dynamic correlation in the motion of individual electrons, and it makes DFT dominant over the conventional Hartree-Fock(HF) producer[23].

Genistein molecule contains three O-H groups, two are (O7-H22 & O10-H24) benzo ring in the chromone system and one is(O18-H28) phenyl ring system. In both IR and Raman, vibrations 84 and 83 assigned for O10-H24 and O18-H28 (3701, 3700 cm⁻¹) respectively and Vibration 77 assigned for O7-H22 (3202 cm⁻¹) at B3LYP level. The

O7-H22 bond vibration wave number is lower than other -OH groups, which explained the electronic behavior of the molecule and confirmed that the hydroxyl group forms a strong hydrogen bond between the phenolic hydrogen atom and the negatively charged carbonyl oxygen atom.

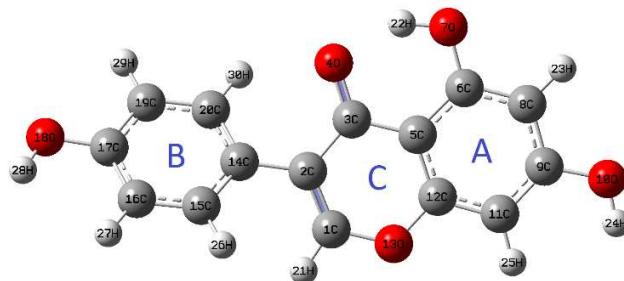

Fig.1. Molecular structure of the genistein molecule calculated with the DFT(B3LYP)/6-311G level.

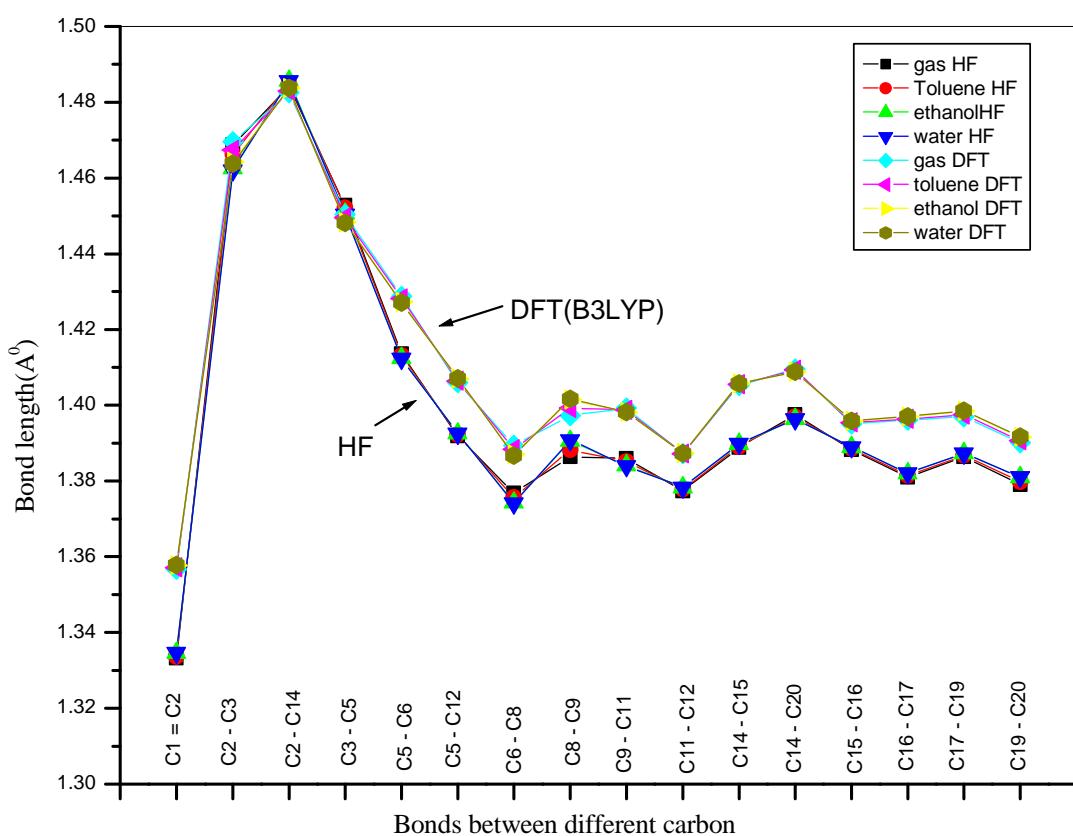

Fig.2. Theoretical calculated bond lengths between different carbon - carbon atoms at HF and B3LYP/6-311G level in different solvents

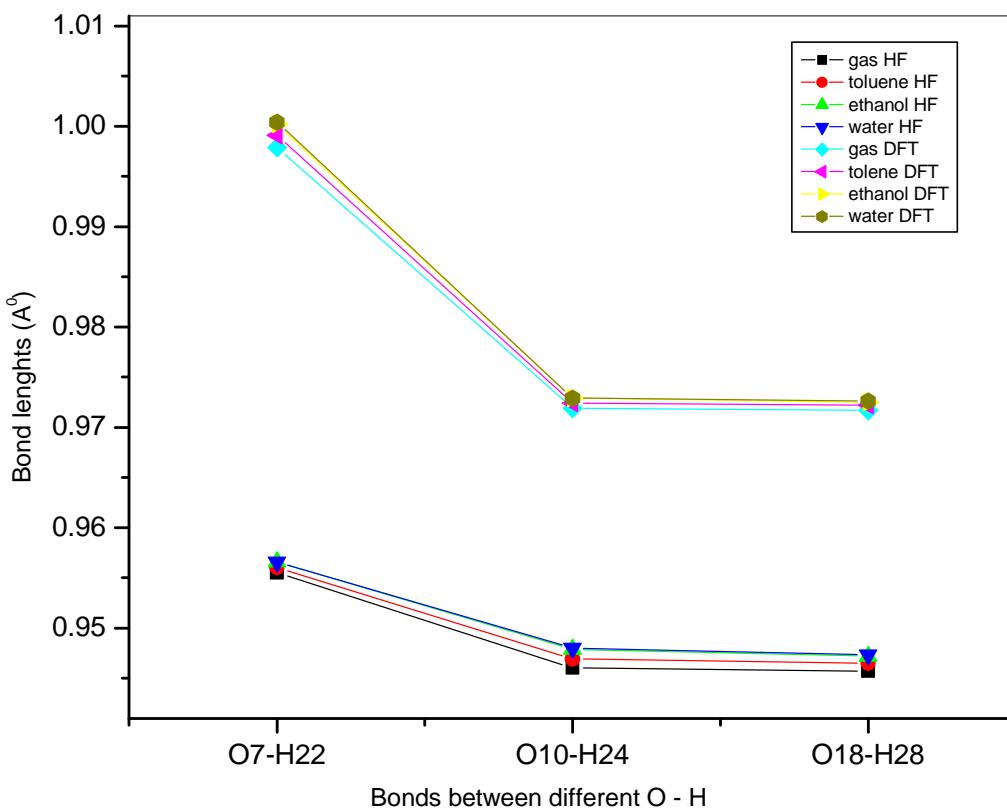

Fig.3. Theoretical calculated bond lengths between different oxygen - hydrogen atoms at HF and B3LYP/6-311G level in different solvents

The vibration modes 84,83 and 82 assigned for O10-H24, O18-H28 and O7-H22($4089, 4086, 3883\text{cm}^{-1}$) respectively at HF level. The Raman intensities are higher than IR intensities in all cases. The C-H stretching vibration modes are assigned 81-75 and 81-75(expect 77) in the range of $3425\text{-}3325\text{ cm}^{-1}$ and $3245\text{-}3156\text{ cm}^{-1}$ at HF and DFT levels respectively. The C-H stretching modes usually appear with strong Raman intensity and are highly polarized. The band predicted by DFT to be at 1613 cm^{-1} (v70),attributed to the C=O stretch is either too weak or blended with the more intense 1583 cm^{-1} (v69)peak to be observed. Both intense bands 1634 and 1695 cm^{-1} involve ring quinoid-like stretches in addition to C=O stretches. The weaker band at 1476 cm^{-1} (v66) also involves considerable OH inplane bending. In all the previously studied flavones the most intense lines were those near 1600 cm^{-1} , which represented the C=O and C₂=C₃stretching region. The vibrations modes at 1434 and 1328 cm^{-1} assigned for O-H in-plane bending and CH bending vibrations. The most intensive lines at 1695cm^{-1} (v74) is assigned O7-H22 bend and Ring a quinoid stretching and at 1179cm^{-1} (v51) is assigned for O18-H28 bending vibration. The prominent band at 392 cm^{-1} (v15) and 360cm^{-1} (v13) involves mostly O-H out of plane bends. The range of 523 to 675cm^{-1} is assigned for Rings deformations. The bands in the region from 1400 to 1600 cm^{-1} are associated with aromatic in-plane skeletal vibrations, double bond character of the carbonyl group and the aromatic character of the pyrone ring, i.e. the overlapping of C = O with C = C. Note also that, except for the band at 1558 cm^{-1} (v68), all the bands between 1476 and 1613 cm^{-1} involve the C = O stretch and the C₂ = C₃stretch, with some degree of O-H bend.

Solvent effect

The results in Table 2 and 3 indicate that solvents have effects on the peak locations of Vibrational modes shift higher and lower values. In general the more polar the solvent is, the larger effect it has. But some modes, the difference between the frequency shifts in different solvents are maximum 12 cm^{-1} indicating that these solvents have essentially the same effect on these Vibrational modes of genistein. From the comparison of the frequency

intensities in solutions with these in gas phase, it can be seen that the intensities of IR and Raman intensities are increase.

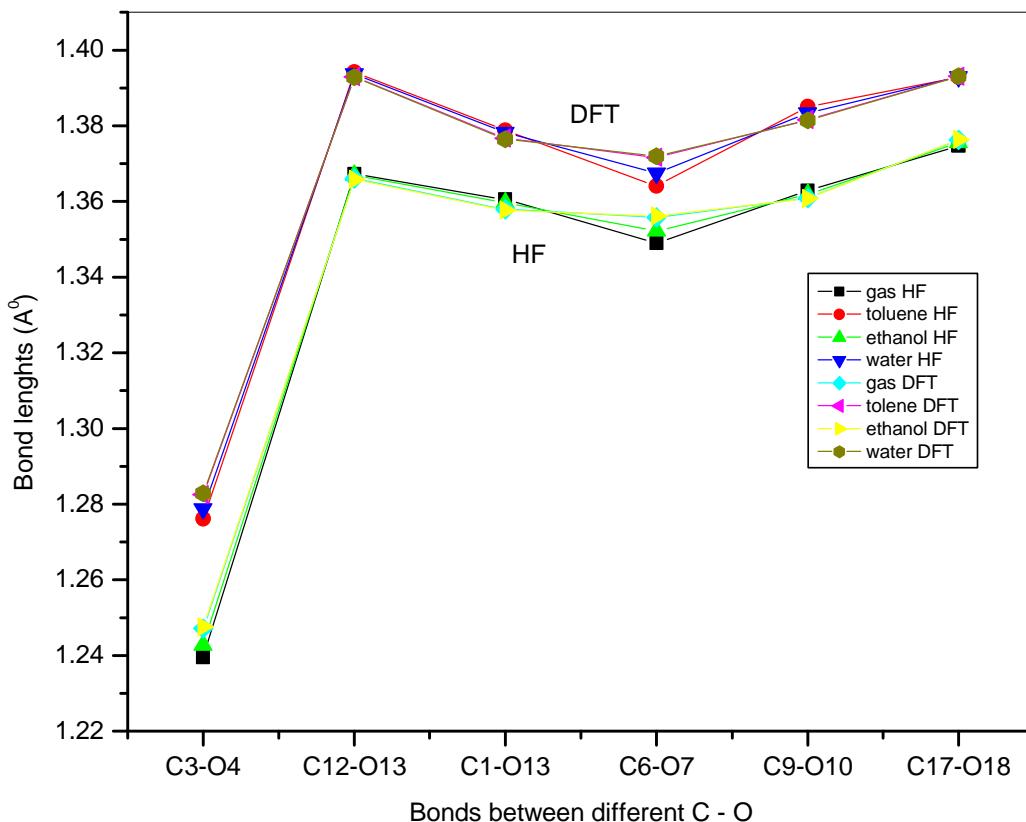

Fig.4. Theoretical calculated bond lengths between different carbon - oxygen atoms at HF and B3LYP/6-311G levelin different solvents

Other molecular properties

Mulliken charges

The calculation of effective atomic charges plays an important role in the application of quantum mechanical calculations to molecular systems. The net atomic charges of Gensitien in various solvents by using Mulliken population Analysis (MPA) method[24], finding the evidence of charge transfer and polarization. The Mulliken charges calculated different levels and in media listed in table 3. The results can, however, better be represented in graphical form as has been given in figure 5. The significant influences of the solvents on the atomic charges are observed from the calculation. The atomic charges are increase with increasing solvent polarity from toluene to ethanol to water, the values of atomic charges in ethanol are large variation in HF method but not in DFT. All carbon atoms making bond with oxygen atom have positive excess charge, the rest of the carbon atoms have negative excess charges accumulation. The C14 atom have very low value in all cases, because of it is a tertiary carbon.

The dipole moment of Gensitien computed at HF and DFT(B3LYP)/6-311G level, increases as the dielectric constant of the medium increases as shown in table 3.the dipole moment is related to the hydrogen bonding iteration. When the solute interacts with solvent, the high electrostatic interaction and large polarization can be induced by the stronger hydrogen bonding interaction between solute and solvent.

Thermodynamic parameters

Tables 4 summarize energies of the optimized structures of the title compounds obtained by HF and DFT/B3LYP method in the gas phase, in toluene, ethanol and water. Further, some calculated thermodynamic parameters are presented in Table (4).The total energies obtained at the B3LYP level is the lowest for each solvent and that obtained at HF level is the highest. Analyzing the results of the thermodynamic functions we see that the total energies and ZPVE decrease with increase solvent polarity other hand enthalpies and entropies are increase with increase solvent polarity.

CONCLUSION

The equilibrium geometry of genistein has been obtained at HF and B3LYP levels of theory using the 6-311G basis set in different solvents. Comparing bond lengths of B3LYP with those of HF as a whole, the formers are on higher side than the later and both the methods have performed nearly to the same level across the bond angles sets. Attempts have been made for the proper frequency assignments for the compound genistein in different solvents. The results shows that the frequency values at HF level are higher than the DFT method. The solvents have effects on the peak locations of Vibrational modes shift higher and lower values, the difference between the frequency shifts in different solvents are maximum 12 cm^{-1} indicating that these solvents have essentially the same effect on these Vibrational modes of genistein. In addition Mulliken charges and dipole movements of the titled compound at different levels were calculated in different solvents and discussed.
